

Convergent Geometric Motifs in Recent Fundamental Physics: Minkowski-First Comparison with Scalar–Angular–Torsion (SAT)

Nathan McKnight

R1 working draft — 23 September 2026

SANDBOXED WORKING PAPER. This manuscript is tentative and intended for scientific criticism. Similarity, correspondence, convergence, or synthesis discussed here is not evidence that SAT is physically correct, nor is numerical or structural agreement treated as derivation or validation.

Abstract

Several recent and largely independent research programs have emphasized structures that are usually discussed separately: non-orientable compactification and lower-dimensional discrete-symmetry breaking; consistent coupling of classical spacetime to quantum matter; exact global closure arising from commensurable continuous quantum evolution; and closed-path holonomy capable of reversing a physical orientation. A separate higher-geometric program, Hypothesis H, proposes cohomotopical charge quantization for the M-theory C-field and develops systematic relations among branes, topology, generalized cohomology, and dimensional reduction. This paper asks a deliberately limited comparative question. If these motifs are synthesized without first invoking Scalar–Angular–Torsion (SAT), what structural picture results, and how closely does that picture resemble the documented Minkowski-first SAT program? Using “structural convergence” only for independently sourced motifs that satisfy the explicit comparison criteria below—not for shared vocabulary alone—we find a nontrivial convergence at the level of geometry/topology, continuous transport, closure/holonomy, orientation, and emergent effective distinctions. We do not claim equivalence among the cited theories, influence between them and SAT, or a derivation of SAT from them. We further formulate, but do not establish, a sharper question: whether SAT can be realized as a four-dimensional effective sector, dimensional reduction, or compactified shadow of a Hypothesis-H-like higher-geometric construction. The comparison is presented as a provenance-sensitive research program and a set of concrete mathematical tests rather than as a validation claim.

1 Introduction

A recurring problem in foundational physics is that structures which appear independent at one descriptive level may become aspects of a common geometric construction at another. Recent work has supplied several examples from directions that are not, on their face, parts of one program. Greene, Kabat, Levin and Porrati study non-orientable compactification and the emergence of lower-dimensional discrete-symmetry breaking. Oppenheim and Sajjad analyze a consistent coupling of quantum matter to classical spacetime and, in a weak-field treatment, linearize around Minkowski spacetime. Carroll, Diachenko and Dulani study exact cyclicity when quantum energy differences are commensurable. Susskind analyzes a closed path in de Sitter space whose

holonomy reverses the orientation of a physical clock. Separately, the Sati–Schreiber Hypothesis H program places branes, higher gauge structure, generalized cohomology and dimensional reduction in a higher-geometric framework.

The present paper does not propose that these programs are equivalent. Nor does it claim that any author above has derived, endorsed or been influenced by Scalar–Angular–Torsion (SAT). Instead we ask a controlled synthesis question: if the relevant structural motifs are first stated in their own terms, without SAT vocabulary, what kind of composite picture do they suggest? Only after that synthesis is stated do we compare it with SAT, a Minkowski-first geometric research program whose documented lineage includes moving-section/intersection constructions by March 2024 and later explicit SAT formulations.

This ordering matters. It makes the comparison falsifiable at the level appropriate to a structural paper. The outside synthesis can fail to resemble SAT; the resemblance can be superficial; or the mapping can expose concrete mathematical questions whose answers distinguish analogy from reduction. We therefore treat convergence as a research prompt, not as evidence for physical correctness.

2 Four contemporary motifs

2.1 Topology and lower-dimensional discrete symmetries

Greene, Kabat, Levin and Porrati show that compactification on a non-orientable internal space can generate lower-dimensional violations of parity, charge conjugation and their product. Their construction is valuable here not because SAT uses the same compactification, but because it gives an explicit modern example in which orientation/topology at one level appears as a physical discrete distinction at another. A related Klein-bottle cosmology develops the dynamical consequences of the same family of ideas.

2.2 Classical spacetime coupled to quantum matter

Oppenheim and Sajjad develop stochastic modes in postquantum classical gravity. Their framework is not SAT: stochasticity is fundamental to their construction and their consistency conditions belong to a different formal program. For the narrower comparison used here, the work provides a concrete formal example in which classical spacetime is coupled consistently to quantum matter within that framework; it does not establish the universal claim that spacetime need never be quantized. Their weak-field analysis around Minkowski space is particularly useful for a comparison whose reference geometry is Minkowskian.

2.3 Closure from commensurable continuous evolution

Carroll, Diachenko and Dulani analyze exact cyclicity in quantum systems whose relevant energy differences are commensurable. The point used here is narrow: exact global recurrence can arise from continuous unitary evolution subject to arithmetic closure conditions. Discreteness in the global observable behavior therefore need not imply a discrete underlying temporal substrate.

2.4 Closed-path holonomy and orientation reversal

Susskind considers time reversal in de Sitter space as a spontaneously broken gauge symmetry and identifies a closed curve whose holonomy reverses the orientation of a physical clock. This supplies an especially clean instance of a distinction that matters throughout geometric model building:

endpoint closure of a path is not the same object as the transformation accumulated by transport around that path. Closed-path transport can carry physically meaningful orientation information.

3 The SAT-free synthesis

Taken together, and without yet importing SAT terminology, the preceding works motivate a limited structural synthesis. The following arrow is our comparison object, not an equation or theorem extracted from any cited paper:

$$\boxed{\text{geometry/topology} + \text{continuous evolution and transport} + \text{closure/holonomy} + \text{orientation structure}; \longrightarrow; \text{effectiveness}} \quad (1)$$

This expression is not a combined theory and is not a claim that the cited formalisms can simply be added. It is a statement about recurring structural motifs. Each term is instantiated differently in the source programs. The synthesis is therefore categorical rather than algebraic: it identifies a family resemblance whose significance must be tested by explicit maps.

Three cautions are essential. First, the arrow does not mean that all physical distinctions are emergent from geometry. Second, it does not mean that any one cited paper contains the full boxed structure. Third, it does not establish that two uses of words such as “holonomy,” “orientation” or “closure” refer to identical mathematical objects. The purpose of the synthesis is precisely to make those possible correspondences explicit enough to test.

4 SAT as a comparison object

The recoverable SAT lineage contains a contemporaneous 23 March 2024 moving-section construction in which extended straight, helical and intertwined paths generate lower-dimensional point-motion readouts [9]. A surviving Fundamental Intuitions document self-dates its SAT filament/time-surface/intersection framework to 2 February 2025 while also carrying a 26 February 2026 update marker [10]. These sources document a developing geometric program; they do not license back-projection of every mature SAT/H(s)H concept into the earlier material.

For the present comparison, the documented early lineage supports extended paths and lower-dimensional intersection/readout constructions [9], while the surviving Fundamental Intuitions source supports a later filament/time-surface/intersection formulation [10]. We do not use those sources to assign mature worldtube, braiding, holonomy, or recurrent-sector language to the earlier strata. This history is not a completed derivation of the Standard Model, general relativity or quantum field theory. Several historical SAT numerical and formal claims have subsequently been downgraded or reopened under audit. The relevant comparison is therefore architectural, not evidentiary.

At that architectural level, the overlap with the SAT-free synthesis is direct enough to merit explicit study. The documented constructions used here motivate asking whether some distinctions normally introduced as separate physical labels can instead be represented through geometric state or observer/readout intersection. The stronger possibilities involving orientation, transport, closure, holonomy, or emergent discrete sectors are treated below as comparison targets and tests, not as historical or current-doctrine claims established by [9]–[10]. This is structurally close to the boxed synthesis even though the component mathematics and physical commitments differ.

The comparison can be summarized as a correspondence problem rather than an identity claim:

Outside motif	SAT analogue	Required test
twist, chirality, intersection/readout sector	construct an explicit map and identify invariant content classical spacetime participates in quantum phenomenology	orientation/topology induces lower-dimensional distinction Minkowski-first continuous background with emergent discrete sectors
specify dynamics and benchmark against quantum constraints commensurability gives exact recurrence	winding/closure/recurrent-mode quantization	derive spectrum rather than fit correspondence closed path carries nontrivial holonomy
phase/twist/transport around recurrent geometric structures	separate endpoint closure from connection-dependent transport	

The last row is particularly important. A geometric loop that returns to its starting point need not possess nontrivial holonomy; holonomy requires a specified connection or transport law. Any SAT/H(s)H use of holonomy must therefore state the transported object, connection and path. This distinction prevents a visual closed curve from being mistaken for a dynamical result.

5 Hypothesis H and the higher-geometric direction

The preceding comparison is bottom-up: several recent results are placed side by side and then compared with SAT. Hypothesis H supplies a possible top-down direction.

Hypothesis H is associated principally with Hisham Sati and Urs Schreiber, with important related formulations by Domenico Fiorenza and collaborators. In its characteristic form, it proposes that the M-theory C-field is charge-quantized in a suitably twisted cohomotopy theory. The program organizes brane charges, higher gauge structures, equivariance and dimensional relationships using higher-geometric and homotopical machinery. It therefore already contains mathematically controlled notions of descent, reduction and compactification rather than using those terms merely as visual analogies.

Nothing in those source results by itself identifies SAT as such a reduction. The next step is a new comparative conjecture posed by this paper:

$$\mathcal{H}_{\text{higher}}; \xrightarrow{;\mathcal{R}_4;?;}; \mathcal{S}_{\text{SAT}}^{3+1}, \quad (2)$$

where $\mathcal{H}_{\text{higher}}$ denotes an appropriately selected Hypothesis-H-like higher-geometric structure. Here $\mathcal{R}_4$ is only a placeholder name for the map that would have to be constructed; no domain/codomain functorial structure or reduction prescription is being assumed. The question mark is substantive. No such map is established here.

The comparison becomes meaningful only if $\mathcal{R}_4$ can be defined so that identifiable SAT structures arise as images, sections, effective degrees of freedom or controlled approximations of higher-geometric objects. A successful construction would need, at minimum, to specify the higher-dimensional domain, compactification/reduction data, surviving four-dimensional fields or geometric degrees of freedom, correspondence of charge/topological sectors, and the dynamics of the reduced theory. Merely drawing similar braids or invoking cohomology is insufficient.

Accordingly, the strongest statement currently warranted is that SAT may be investigated as a candidate four-dimensional effective realization, reduction or compactified shadow of a Hypothesis-H-like synthesis. Determining whether compactification,” dimensional reduction,” effective sector,”

truncation,” or only “structural shadow” is correct is a concrete mathematical task rather than a terminological preference.

6 Provenance and the meaning of convergence

The comparison is potentially interesting only if chronology and provenance remain explicit. The recoverable SAT record contains the contemporaneous 23 March 2024 moving-section construction described above [9]; a Fundamental Intuitions stratum dated 2 February 2025 in a surviving document marked updated 26 February 2026 [10]; and a contemporaneous 28 December 2025 archive-release record publicly presenting the SAT 2023–25 repository as a working public archive, with first-party Git history independently recording substantive uploads that day [11]. These dates establish documented states in the SAT lineage; they do not establish scientific correctness, blanket priority, exhaustive independence from older mathematical antecedents, or identity between historical SAT and mature H(s)H.

The 28 December 2025 milestone is a public archive release/presentation [11], not the repository-creation date and not, on the evidence used here, a claim that every later archive artifact was already present. Likewise, the surviving Fundamental Intuitions text is an updated edition [10] rather than a frozen sentence-for-sentence snapshot of 2 February 2025.

The recent comparison papers establish the content and chronology of their authors’ programs. Where SAT material predates the specific recent papers compared here, that is a bounded chronology statement, not an exhaustive independence claim. We therefore describe SAT as developed on a documented lineage predating the recent papers compared here, without claiming here that it was independent of all older mathematical or physical antecedents.

The relevant observation is the recent proliferation of structurally convergent motifs: topology generating effective distinctions, classical geometric backgrounds participating in quantum descriptions, closure emerging from continuous evolution, and orientation data carried by transport. This distinction avoids two opposite errors. One would be to treat every familiar geometric ingredient as novel to SAT. The other would be to dismiss a potentially informative convergence merely because each ingredient has antecedents. Novelty, if present, may reside in a specific synthesis, dependency structure, reduction map or predictive consequence rather than in any isolated motif.

A dedicated prior-art audit should therefore follow rather than precede the blind contemporary synthesis used here. That audit should identify earlier instances of the same mathematical mechanisms, determine which apparent correspondences are standard consequences of known geometry, and revise novelty language accordingly. Until that audit is complete, this manuscript remains explicitly sandboxed.

7 Tests that could strengthen or dissolve the comparison

The synthesis becomes scientifically useful only where it generates discriminating work. We identify five immediate tests.

1. Object-level dictionary. For every proposed correspondence, specify the mathematical object on both sides: manifold, bundle, connection, section, worldline/worldtube, homotopy class, observable or effective field. Reject correspondences that survive only as shared vocabulary.

2. Reduction test. Attempt an explicit $\mathcal{R}_4$ from a narrowly chosen Hypothesis-H construction. If no controlled reduction yields anything resembling the SAT state space, the compactification

language should be abandoned in favor of weaker structural comparison.

3. Holonomy test. Define the SAT/H(s)H connection and transported object. Compute transport around a controlled closed path and separate path-dependent holonomy from trivial endpoint-frame telescoping. Compare the resulting invariant with the role played by holonomy in the external examples.

4. Emergent-discreteness test. Starting from continuous SAT/H(s)H geometry, derive rather than stipulate at least one discrete spectrum or sector from closure/topology and compare it with the corresponding established physical observable. Parameter freedom and post-hoc normalization must be exposed.

5. Benchmark and failure test. For any claimed physical correspondence, compare the geometric construction against the standard theory on the same observable, including known null results and precision constraints. Numerical agreement is not derivation; failure to reproduce established behavior is informative.

These tests are intentionally capable of weakening the thesis. A useful structural synthesis should tell us not only where to look for agreement but also how to discover that the resemblance was superficial.

8 Discussion

The contemporary literature considered here does not form a hidden consensus theory. The papers have different assumptions, mathematical languages and physical goals. Their juxtaposition nevertheless highlights a recurring strategy: shift explanatory weight from separately stipulated physical labels toward geometry, topology, global consistency and transport.

SAT is an unusually direct comparison object because its organizing question has long been whether known physics can be mapped into a Minkowski-first geometric representation of extended histories and their readout. The resulting resemblance is strongest at the level of architecture and weakest where SAT still lacks explicit derivations: gauge structure, quantum dynamics, operational observables and precision phenomenology. That asymmetry should be treated as a guide to work rather than concealed.

Hypothesis H changes the comparison in a useful way. Instead of asking only whether recent bottom-up results happen to resemble SAT, it asks whether a mature higher-geometric framework contains a route by which SAT-like four-dimensional structures could arise as reduced or effective objects. If such a route exists, the relationship would be substantially more informative than motif matching. If it does not, the failure will sharply delimit the comparison.

The proliferation of these motifs is therefore worth recording without inflating it into validation. Geometry-first and topology-first explanations are appearing in multiple contemporary contexts. SAT occupies nearby conceptual territory on a documented lineage. The next question is mathematical: whether the resemblance can be promoted to explicit maps, reductions and derived observables.

9 Conclusion

When several recent foundational results are synthesized at a deliberately structural level, they suggest a picture in which geometry and topology, continuous transport, global closure and orientation

can generate effective physical distinctions. SAT exhibits a documented architectural resemblance to that picture. The resemblance is substantive enough to motivate explicit mathematical tests but not strong enough to establish equivalence, derivation, novelty or physical correctness.

The most ambitious next question is whether SAT can be obtained as a controlled four-dimensional reduction or effective sector of a Hypothesis-H-like higher-geometric construction. That question is currently open. Answering it requires an explicit reduction map, a dictionary of mathematical objects, and derived observables that survive comparison with established physics.

The useful claim of this paper is therefore modest but actionable: a set of recent results, when placed in a provenance-aware structural synthesis, converges on a geometric pattern unusually close to the organizing architecture of SAT. The appropriate response is neither validation nor dismissal, but calculation.
